Supporting Information

ABSTRACT: A variety of PbI₂/MAPbI₃ perovskites were prepared and investigated by a rapid screening technique utilizing a modified scanning electrochemical microscope (SECM) in order to determine how excess PbI₂ affects its photoelectrochemical (PEC) properties. An optimum ratio of 2.5% PbI₂/MAPbI₃ was found to enhance photocurrent over pristine MAPbI₃ on a spot array electrode under irradiation. With bulk films of various PbI₂/MAPbI₃ composites prepared by a spin-coating technique of mixed precursors and a one-step annealing process, the 2.5% PbI₂/MAPbI₃ produced an increased photocurrent density compared to pristine MAPbI₃ for 2 mM benzoquinone (BQ) reduction at −0.4 V vs FeCl₃/FeCl₆. As a result of the relatively high quantum yield of MAPbI₃, a time-resolved photoluminescence quenching experiment could be applied to determine electron–hole diffusion coefficients and diffusion lengths of PbI₂/MAPbI₃ composites, respectively. The diffusion coefficients combined with the exciton lifetime of the pristine 2.5% PbI₂/MAPbI₃ (τPL = 103.3 ns) give the electron and hole exciton diffusion lengths, ~300 nm. Thus, the 2.5% PbI₂/MAPbI₃ led to an approximately 3.0-fold increase in the diffusion length compared to a previous report of ~100 nm for the pristine MAPbI₃ perovskite. We then demonstrated that the efficiency of liquid-junction solar cells for 2.5% excess PbI₂ of p-MAPbI₃ was improved from 6.0% to 7.3%.

INTRODUCTION

Organic–inorganic hybrid lead-based perovskites exhibit remarkable properties, including high absorption coefficients, long exciton lifetimes and diffusion lengths, high charge-carrier mobilities, and low exciton binding energies.¹⁻⁴ and have yielded power conversion efficiencies (PCE) of ~20% in photovoltaic cells.⁵⁻⁸ These photovoltaic cells usually are titanium dioxide (TiO₂) dye-sensitized solar cells (DSSC)⁹,¹⁰ and solid-state solar cells.¹¹⁻¹⁷ In a previous paper, we described liquid junction PEC cells involving MAPbI₃ perovskites.¹⁸ The MAPbI₃ perovskites are extremely sensitive to moisture¹⁹ and unstable in polar solvents. However, dichloromethane (CH₂Cl₂) can be used for liquid junction PEC solar cells with reasonable stability because of its relatively higher dielectric constant and is also useful for fundamental studies.¹⁸ More importantly, the use of liquid electrolytes allows easy combinatorial synthesis and screening of new perovskite materials in arrays and testing the effects of various dopants on them. In this article, we describe such studies using robotic synthesis and rapid screening based on scanning electrochemical microscopy (SECM).

MAPbI₃ perovskites were synthesized with equimolar mixture of MAI and PbI₂. Dittrich et al. showed excess PbI₂ can be used to passivate perovskite grain boundaries and decrease carrier recombination lifetime for improving the performance of perovskite-based solar cells.¹⁰ Burda et al. then confirmed this passivation effect of excess PbI₂ by femtosecond time-resolved transient absorption spectroscopy (fs-TA) of MAPbI₃ perovskite films.¹¹ The peak intensities of perovskite TA were used to estimate relative amounts of excess PbI₂ in the samples, while powder X-ray diffraction (XRD) can independently confirm the existence of excess PbI₂. Time-resolved transient absorption demonstrated that perovskite films with less excess PbI₂ displayed faster relaxation rates. These fast dynamics are assigned to charge carrier trapping at perovskite grain boundaries, and the slower dynamics in samples containing PbI₂ are attributed to a passivation effect.¹² However, these studies did not show the amount of PbI₂ required for optimal passivation. Here, our contribution is to screen different quantitative combinations of PbI₂ and MAPbI₃ perovskites efficiently utilizing SECM imaging.

EXPERIMENTAL SECTION

Materials. Methylamine (CH₃NH₂, 2 M in methanol, Alfa Aesar), hydroiodic acid (HI, 57 wt % in water, Alfa Aesar), lead iodide (PbI₂, 99.9985% metals basis, Alfa Aesar), N,N-dimethylformamide (DMF, ≥99.9%, Sigma-Aldrich), methylene chloride (CH₂Cl₂, anhydrous, ≥99.9%, Sigma-Aldrich), tetrahydrofuran (THF, anhydrous, ≥99.9%, Sigma-Aldrich), ethyl acetate (EA, anhydrous, ≥99.8%, Sigma-Aldrich), p-benzoquinone (BQ, ≥99.5%, Sigma-Aldrich), tetrabutylammonium

hexafluorophosphate (TBAPF$_6$ ≥ 99.9%, Sigma-Aldrich). Fluorine doped tin oxide (FTO) coated glass was obtained from Pilkington (Toledo, OH) as a substrate of the electrodes. The 15 × 15 mm squares were cleaned by successive sonication in ethanol and 2-propanol and rinsed with deionized water. Phenyl-C61-butyric acid methyl ester (PCBM; Solenne BV) and 2,2′,7,7′-tetракис(N,N-ди-p-метилксифениламин)9,9′-спироби-флуоре (спиро-ОМеТАД; Borun Chemicals).

Preparation of Perovskite Film. p-MAPbI$_3$ was spin-coated on FTO glass substrates from N,N-dimethylformamide (DMF) (Alfa Aesar) solution with the mixture of MAI and PbI$_2$. The weight percent of excess PbI$_2$ to MAPbI$_3$ was increased in the order of 0%, 1%, 2.5%, 5%, 7.5%, 10%, and 15%. MAI was synthesized by stirring 27.86 mL of methylamine (2 M in methanol, Alfa Aesar) and 30 mL of hydroiodic acid (57 wt % in water, Alfa Aesar) in 250 mL round bottomed flask in an ice bath under an argon atmosphere for 3 h. After the reaction, the solvent was evaporated using a rotary evaporator. A white powder, methylammonium iodide (MAI), was washed with diethyl ether by stirring the solution for 30 min, which was repeated three times and then finally dried at 60 °C in vacuum oven for 24 h. The synthesized MAI white powder was mixed with PbI$_2$ (Alfa Aesar) in DMF at 100 °C for 1 h. The top quenchers were then deposited in air via spin-coating chlorobenzene solutions with the following conditions: PCBM at 30 mg/mL spin-coated at 1000 rpm and spiro-OMeTAD at 0.46 M spin-coated at 2000 rpm.

Preparation of Photocatalyst Spot Array Electrodes. Spot array electrodes (an electrode composed of spots with each spot having a different composition) were fabricated using a previously reported method$^{22}$ using a CH Instruments dispenser. The precursor solutions (0.518 M in DMF) were dispensed onto the FTO substrate to create the spot array electrode. This was done by moving the piezo-dispensing tip to a programmed position over the FTO substrate and dispensing drops (~100 pL/drop) of the precursor solutions. The PbI$_2$ precursor solution was dispensed first in a preprogrammed pattern onto the FTO substrate, followed by a second MAI precursor solution dispensed onto the FTO in an overlay pattern. The distance between photocatalyst spots on the array was about 150 μm with a spot diameter of approximately 350 μm. Each spot had a total of 25 drops, and the spot composition is reported as the relative number of drops of each precursor solution. In all cases, the composition of the excess PbI$_2$ was controlled from 0 to 15 wt % PbI$_2$ to MAPbI$_3$ ratio. The prepared arrays were annealed at 100 °C for 1 h in air to form the MAPbI$_3$ perovskites.

Screening the Spot Array Electrodes. A schematic SECM setup has been described previously.$^{25}$ Briefly, a 400 μm diameter optical fiber was connected to a 150 W xenon lamp (Oriel) and was attached to the tip holder of a CHI 900B SECM. A 420 nm long-pass filter (removing the UV portion of the spectrum) was used for visible light only illumination in rapid screening experiments. The perovskite array was used as the working electrode and was placed in the bottom of a custom designed Teflon SECM cell with an O-ring (exposed area: 1.0 cm$^2$). A Pt wire was used as the counter electrode, and a saturated Ag/AgNO$_3$ electrode was used as the reference electrode. The electrolyte consisted of 2 mM BQ and 0.1 M TBAPF$_6$ (supporting electrolyte). Light from the xenon lamp was passed through the optical fiber, positioned perpendicular to the working electrode ~200 μm above the surface, to illuminate one spot on the working electrode at a time. The optical fiber tip was scanned across the spot array electrode with a scan rate of 500 μm/s, while a potential of −0.4 V vs Ag/AgNO$_3$ was applied to the working electrode through the SECM potentiostat. Scanning over the spot arrays revealed two-dimensional images indicative of the generation of photocurrent on each spot.

Photoelectrochemical Measurements. The results on array electrodes were confirmed by PEC of perovskite films. The photoactivity of p-MAPbI$_3$ was measured in a photoelectrochemical cell. The films were used as working electrodes (0.27 cm$^2$) exposed to electrolyte solution and irradiation. All measurements were carried out in a borosilicate glass cell with a carbon counter electrode and Ag/AgNO$_3$ reference electrode (a silver wire immersed in 0.01 M silver nitrate in MeCN connected to the cell via a 0.10 M TBAPF$_6$ in deaerated CH$_2$Cl$_2$ salt bridge).$^{18}$ All potentials are reported vs Fc/Fc$^+$ in deaerated CH$_2$Cl$_2$. The light source was irradiated through the electrolyte solution using full output of the Xe lamp with an incident light intensity of about 100 mW/cm$^2$. The supporting electrolyte was 0.1 M TBAPF$_6$ in deaerated CH$_2$Cl$_2$.

Instruments. A CH Instruments Model 760E photochemical analyzer (Austin, TX) was used as a potentiostat for the experiments with the thin film electrodes. Illumination was with a xenon lamp (XBO 150 W, Osram) at full output for UV-visible irradiation. Glancing incidence angle X-ray diffraction (XRD) measurements were performed by using D8 ADVANCE (Bruker, Fitchburg, WI) equipped with a Cu Kα radiation source where the incident angle was 0.4°. The film thickness was measured by scanning electron microscopy (SEM, Quanta 650 FEG, FEI Company, Inc., Hillsboro, OR). In the solar cell measurements, current (I) and voltage (V) readings were taken between the working electrode and the carbon counter electrode without external power source using a Keithley Model 2400 electrometer and a xenon lamp solar simulator (Newport) equipped with an AM1.5G filter. Emission spectra were obtained by a front-face alignment on a Fluorolog-3 spectrophotometer (Jobin-Yvon) spectrophotometer. For precursor dispensing, a CH Instruments model 1550 dispenser (Austin, TX) with a piezoelectric dispensing tip (MicroJet AB-01-60, MicroFab, Plano, TX) connected to an XYZ stage driven by a computer-controlled stepper-motor system (Newport) was used.

RESULTS AND DISCUSSION

SECM Scanning of Perovskite Arrays. A method for rapid screening of semiconductor materials using a form of the modified SECM has been described previously.$^{26}$ In brief, arrays composed of ~350 μm diameter semiconductor spots with different compositions were deposited by a piezoelectric dispenser onto a conductive fluorine-doped tin oxide (FTO) substrate. The scanning tip of the modified SECM was replaced by a 300 μm fiber optic connected to a xenon lamp and was rapidly scanned over the array. This combinatorial screening technique can reduce the effort and material expended in the optimization process,$^{27,28}$ and evaluate the photocurrent response at the substrate of different elements in the semiconductor array.$^{3}$ In this study, we performed a rapid screening analysis on PbI$_2$/MAPbI$_3$ composites with modified SECM. The arrays contained three rows and seven spots of columns. To test the reproducibility, the first and second seven-spot rows are pristine MAPbI$_3$ perovskites. The photocurrents of all 14 spots are almost the same (~5.6 ± 0.1 μA). The third seven-spot row we analyzed are spot arrays of MAPbI$_3$ perovskite blended with varying excess amounts of the PbI$_2$ precursor in compositions ranging
from 0 to 15%. Time-resolved photoluminescence spectra on separate films at different concentrations were then monitored for the different ratios of PbI\textsubscript{2}/MAPbI\textsubscript{3} composites. The SECM imaging and photoluminescence decay kinetics can yield further insight as to which factor primarily affects the resulting enhancement.

While it has been established previously that the maximum photocurrent of photovoltaic devices may be increased by introduction of PbI\textsubscript{2} in MAPbI\textsubscript{3},\textsuperscript{21} SECM rapid screening of PbI\textsubscript{2}/MAPbI\textsubscript{3} composite materials enables determination of the optimum amount of PbI\textsubscript{2} in the MAPbI\textsubscript{3} perovskite. Employing the SECM technique, we screened spot array electrodes to determine the dependence of photocurrent response on composition of PbI\textsubscript{2}/MAPbI\textsubscript{3} composites with PbI\textsubscript{2} content ranging from 0 to 15 wt %. The rapid screening results showed that 2.5\% of excess PbI\textsubscript{2} to MAPbI\textsubscript{3} gave rise to the highest photocurrent improvement under irradiation. When the excess amounts of PbI\textsubscript{2} to MAPbI\textsubscript{3} were more than 10\%, the photocurrents were lower than that of the pristine MAPbI\textsubscript{3}. Figure 1 presents a representative example of the SECM result of a PbI\textsubscript{2}/MAPbI\textsubscript{3} spot array electrode under irradiation. The color represents the measured photocurrent shown in the scale bar above the SECM image. The first and second seven-spot rows are pure MAPbI\textsubscript{3} perovskites. The third seven-spot row represents the amount of excess PbI\textsubscript{2} in each spot in the array electrode. The photocurrent shown is for 2 mM BQ reduction with 0.1 M TBAPF\textsubscript{6} supporting electrolytes in CH\textsubscript{2}Cl\textsubscript{2} measured at an applied potential of −0.4 V vs Fc/Fc\textsuperscript{+}. The third seven-spot row represents the amount of excess PbI\textsubscript{2} in each spot in the array electrode. The photocurrent shown is for 2 mM BQ reduction with 0.1 M TBAPF\textsubscript{6} supporting electrolytes in CH\textsubscript{2}Cl\textsubscript{2} measured at an applied potential of −0.4 V vs Fc/Fc\textsuperscript{+}.

Characterization and Photoelectrochemistry with Thin Bulk Film Samples. A one-step deposition and annealing process made the MAPbI\textsubscript{3} perovskite films. Varying the amount of excess PbI\textsubscript{2} in MAI solution made MAPbI\textsubscript{3} containing PbI\textsubscript{2}. The compositions of PbI\textsubscript{2}/MAPbI\textsubscript{3} films were characterized by X-ray diffraction (XRD). Without adding excess PbI\textsubscript{2} only the β-phase of the MAPbI\textsubscript{3} is formed (Figure 2).\textsuperscript{30} PbI\textsubscript{2} can be easily detected by the (001) and (003) reflections at 2θ = 12.56° and 39.42°, respectively.\textsuperscript{31} The MAPbI\textsubscript{3} thin-film bulk electrodes were then introduced to characterize the PEC performance in order to verify the results of the rapid SECM screening tests. We compared the PEC responses of MAPbI\textsubscript{3} to 2.5\% PbI\textsubscript{2}/MAPbI\textsubscript{3} and 15\% PbI\textsubscript{2}/MAPbI\textsubscript{3} for BQ reduction by linear sweep voltammetry (LSV) with chopped light under irradiation (Figure 3). In Figure 3, the LSV was conducted from +0.45 to −0.40 V vs Fc/Fc\textsuperscript{+} at a scan rate of 50 mV/s. While the pristine MAPbI\textsubscript{3} resulted in a photocurrent of ∼4.1 mA/cm\textsuperscript{2}, the 2.5\% and 15\% PbI\textsubscript{2}/MAPbI\textsubscript{3} samples generated a photocurrent of 6.8 and 2.0 mA/cm\textsuperscript{2} for BQ reduction, respectively. These results are consistent with those of the SECM screening process illustrated in Figure 1, confirming the validity of the SECM screening technique for determining the dependence of PEC performance on PbI\textsubscript{2}/MAPbI\textsubscript{3} composite composition.

Steady-State Photoluminescence and Photoluminescence Decay Dynamics. Initially the MAPbI\textsubscript{3} film samples were prepared including solution preparation and spin coating. The steady-state photoluminescence spectrum for perovskite films was carried out at room temperature under optical excitation with monochromatic laser light at 485 nm, displayed in Figure 4. The photoluminescence of the MAPbI\textsubscript{3} films showed a strong band at 770 nm with a full width at half-maximum (fwhm) of 130 nm. Photoluminescence decay dynamics can be applied to determine carrier diffusion parameters in the perovskite.
films in the absence and presence of the excess PbI2. Time-resolved photoluminescence spectra of MAPbI3 perovskite films were then recorded by using a time-correlated single photon counting (TCSPC) system to explore the photoluminescence decay dynamics. Excitation was provided by a 485 nm pulsed laser, which provided <200 ps pulses with the fluence of ~30 nJ/cm². The thickness of the MAPbI3 films was approximately 200 nm, which is similar to the typical thickness in photovoltaic devices. The photoluminescence decay at the wavelength of 770 nm was monitored for perovskite films deposited on FTO glass substrates, shown in Figure 5.

Figure 5. Photoluminescence decay monitored at 770 nm for PbI2/MAPbI3 composite perovskite films containing 0.0, 1.0, 2.5, 5.0, 7.5, 10, and 15 wt % of excess PbI2.

The photoluminescence lifetime, \( \tau_{PL} \), was determined by fitting exponential functions to the measured decay curves, as shown in Table 1. The fitting parameters (\( r_1, \alpha_1, \tau_2, \alpha_2 \)) and corresponding errors (\( \chi^2 \)) of photoluminescence decay are summarized in Table S1. For the 2.5% PbI2/MAPbI3, the fast decay component, \( r_1 \), shows a time constant of \( \tau_1 = 9.0 \pm 0.1 \) ns, likely due to bimolecular recombination; the long decay component \( r_2 \) is assigned to recombination of free carriers in the radiative channel, which matches with the previously reported photoluminescence decay in MAPbI3 films. The diffusion lifetime in 2.5% PbI2/MAPbI3 perovskite films was extended to 103.3 ns because the passivation effect results in the reduction of free carrier recombination. The pristine MAPbI3 film exhibits a time constant of \( \tau = 9.10 \) ns owing to electronic defects at grain boundaries that results in a serious recombination with the relatively lower photocurrent density. In comparison with 2.5% PbI2/MAPbI3 perovskite films, the long decay component, \( \tau_2 \), for 5.0% and 7.5% of excess PbI2 in MAPbI3 film decreased slightly to be 101.6 and 86.7 ns, respectively, because the PbI2 might become one of the main phases in the perovskite films. By adding 15% of excess PbI2 in MAPbI3 film, lifetime shortened to a time constant of \( \tau_{PL} = 4.43 \) ns since higher amount of PbI2 becomes an insulating layer rather than a passivating layer.

The crucial parameters for enhancing the efficiency of photovoltaic devices are the diffusion coefficient and the diffusion length, \( D \) and \( L \), which can be determined by photoluminescence quenching measurements. By spin-coating either an electron-accepting fullerene [phenyl-C61-butyric acid methyl ester (PCBM)] or a hole-acceptor [2′,7′-tetrakis-(N,N-di-p-methoxyphenylamine)-9,9-spirobifluorene (Spiro-OMeTAD)] on top of the perovskite films, quenching samples were fabricated. For the addition of electron and hole-quinquers, PCBM and Spiro-OMeTAD, the lifetimes of MAPbI3/PCBM and MAPbI3/Spiro-OMeTAD were decreased with time constants \( \tau_{PL} \) of 2.9 ± 0.1 and 4.0 ± 0.1 ns, respectively (Figure S-1). According to a 1-D diffusion model (equation S3, described in detail in Supporting Information), we calculated total decay rate, \( k = k_r + k_{nr} = \beta \tau s^{-1} \), by using a stretched exponential function to fit photoluminescence decay curves of perovskite films in the absence of any quenchers. The boundary condition \( n(L,t) = 0 \), where \( x = 0 \) at the glass/perovskite interface and \( L \) is the perovskite film thickness, can be obtained by assuming that all charge carriers that reach the interface are quenched. And then we estimated the electron and hole diffusion coefficients, showing 0.010 ± 0.003 and 0.008 ± 0.002 cm²/s, respectively. The electron and hole diffusion lengths (\( L_D \)) were calculated to be \( L_D (c) = 135 \) nm and \( L_D (h) = 85 \) nm by utilizing \( L_D = (D \tau_{PL})^{1/2} \), where \( \tau_{PL} \) is the lifetime in the absence of quenching, tabulated in Table 1. The long transport lengths of MAPbI3 perovskite films are due to its crystal structure containing corner-connected PbI6 octahedral that form a three-dimensional framework. The diffusion length \( L \) measured for the pristine MAPbI3 is close to the typical diffusion length for the MAPbI3 perovskite film (~100 nm). In comparison to pure MAPbI3, the \( L_D (c) \) and \( L_D (h) \) of 2.5% PbI2/MAPbI3 composites are 321 and 287 nm, which reached about 3.0-fold longer diffusion length than the 0% PbI2/MAPbI3 sample. We attribute that this result, a reduction in the number of trapping sites, was due to relling the grain boundaries in the perovskite materials. We then demonstrated that short-circuit current density for 2.5% excess PbI2 of p-MAPbI3 was increased from 7.8 to 9.8 mA/cm², and the efficiency of a liquid-junction solar cell was enhanced from 15% to 18.8%.

Table 1. Fitted Decay Times (\( \tau_{PL} \)) and Diffusion Lengths (\( L_D (c) \) and \( L_D (h) \)) of PbI2/MAPbI3 Composite Perovskite Films Containing 0.0, 1.0, 2.5, 5.0, 7.5, 10, and 15 wt % of Excess PbI2
